# Terrain Model Registration for Single Cycle Instrument Placement

Matthew Deans, Clay Kunz, Randy Sargent, and Liam Pedersen QSS Group / Autonomy and Robotics Area NASA Ames Research Center Mailstop 269-3, Moffett Field, CA 94035, USA {mdeans,ckunz,rsargent,lpedersen}@arc.nasa.gov

#### ABSTRACT

This paper presents an efficient and robust method for registration of terrain models created using stereo vision on a planetary rover. Our approach projects two surface models into a virtual depth map, rendering the models as they would be seen from a single range sensor. Correspondence is established based on which points project to the same location in the virtual range sensor. A robust norm of the deviations in observed depth is used as the objective function, and the algorithm searches for the rigid transformation which minimizes the norm. An initial coarse search is done using rover pose information from odometry and orientation sensing. A fine search is done using Levenberg-Marquardt. Our method enables a planetary rover to keep track of designated science targets as it moves, and to hand off targets from one set of stereo cameras to another. These capabilities are essential for the rover to autonomously approach a science target and place an instrument in contact in a single command cycle.

# I. INTRODUCTION

Single cycle instrument placement (SCIP) is the single greatest autonomy need for the next generation of Mars rovers, such as the planned 2009 MSL rover mission to Mars1. The goal of SCIP is to enable a planetary rover to approach and place an instrument on a scientifically interesting point on the terrain from a distance of 10 meters[1], [2]. This must happen within one command cycle, so that after an operator selects a science target and uploads a command, the next response from the rover is the requested science measurement from the target. Single cycle instrument placement will significantly increase science return per unit of operational time over the stop and move, human-in-the-loop operation of the Sojourner and MER rovers, which each require between 3 and 5 command cycles to obtain the same data.

The first step in SCIP is the navigation of the rover to a location that places the point of interest within the workspace of an arm which carries an instrument. Uncertainty about the exact target position and accumulated rover localization errors require that the rover actively keep track of where the target is in relation to itself as navigates towards it. Once positioned, the rover evaluates

Fig. 1. Artist's conception of 2009 Mars Smart Lander [JPL]

the target to ensure the instrument can be safely placed and then moves it into place with the arm. This can require handing the target off from the cameras used to track it in the approach phase to the cameras used for close up inspection and positioning of the arm.

Terrain model registration can solve both the target tracking and target hand-off problems. Tracking is done by registering successively acquired terrain models of the target area to the initially acquired model of the target. Tracking also provides information about rover motion between views. Hand-off is done by registering the target models from two different sensors.

This paper focuses on the problem of terrain model registration. The method presented in this paper uses stereo vision to build 3D terrain models, then uses an algorithm similar to ICP to find the rigid transformation which aligns two models. An important difference between the method presented here and ICP is the use of a sensor model which projects the two views into a virtual range sensor. Using a rendering model removes the need to search for corresponding points with a distance heuristic. A robust error metric is then minimized, reducing the effect of outliers in the stereo models. A coarse search for the minimum is performed using a correlation based strategy which uses partial knowledge of rover motion. A fine search is performed using a general purpose robust estimation algorithm.

## II. PREVIOUS WORK

The Iterated Closest Point (ICP) algorithm was introduced by Chen and Medioni[3] and Besl and McKay[4] to recover a rigid transformation between two point clouds with unknown correspondence. The method relies on two steps. The first uses a nearest neighbor heuristic to establish correspondence between points. The second computes the rigid transformation between the point clouds. When only two point clouds are being aligned, the second step is computed in closed form.

A good summary of ICP and its extensions can be found in a recent survey[5]. An important extension to ICP is an objective function which uses the distance between a vertex in one model and the nearest point on the surface of the other model, rather than the nearest vertex[6]. This objective function does not penalize for motion of corresponding points along the surface.

Methods other than ICP have also been used for model registration, including the Expectation-Maximization algorithm[7], and nonlinear optimization with robust M-estimators[8]. The latter approach is attractive for several reasons. Fitzgibbon showed that besides increasing the robustness of the solution to outliers in the data, using Levenberg-Marquardt to minimize a robust norm converges to a solution rapidly and has a significantly larger basin of attraction than least squares. For these reasons, robust estimation with Levenberg-Marquardt is used in this work.

## III. APPROACH

This section describes the technical approach used for terrain model registration. The approach relies on three key parts. The first is a sensor model which predicts the observations that should be seen under a hypothesized transformation for the surface models. The sensor model used here is a virtual range sensor, which is a reasonable approximation to the stereo system used to measure the shape of the terrain. The sensor model allows us to write an objective function which depends on the difference between what is observed and what is expected under the hypothesis.

The second part is a coarse search based on approximate knowledge of position and orientation. Assuming a fixed orientation, the virtual range sensor axes specify a coordinate frame over which a 2D correlation search can be performed. The coarse search finds an approximate translation which is closer to the alignment than the initial guess based on odometry.

The third part is a fine search based on Levenberg-Marquardt (LM) nonlinear optimization[9], along with an extension which incorporates robust estimation using iteratively reweighted least squares (IRLS)[10], [11]. The robust optimization method is used to minimize the objective function and recover the alignment of the terrain models.

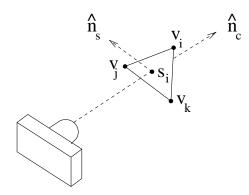

Fig. 2. Each pixel in the range image is predicted by rendering the corresponding mesh facet into a virtual range sensor.

## A. Sensor model

Stereo processing results in a range image consisting of a depth estimate for every pixel in the rover stereo cameras. These depth estimates are combined to produce a 3D model of the surface. If two models of a surface are made from different locations, the rigid transformation that aligns the two models can be used to determine the coordinate transformation between views.

The surface models are represented by triangulated meshes with vertices  ${\bf v}$  and  ${\bf v}'$ . If the two 3D models contain some region of overlap, there is a rigid transformation that aligns the overlapping regions. The goal of registration is to find the rigid transformation that aligns the model  ${\bf v}$  with the model  ${\bf v}'$ . We represent the transformation using the parameter  ${\bf p}=(x,y,z,\alpha,\beta,\gamma)^T$  corresponding to 3 translational and 3 rotational degrees of freedom. There are many ways to represent rotations; we choose Euler angles for simplicity. Singularities in the representation are not an issue since roll and pitch angles for our rover are naturally constrained to be within tolerable physical limits.

These parameter  $\mathbf{p}$  defines a  $4 \times 4$  transformation matrix  $\mathbf{T}_{\mathbf{p}}$ . If  $\mathbf{p}$  is the parameter describing the transformation between surfaces  $\mathbf{v}$  and  $\mathbf{v}'$ , then for every pair of corresponding points  $\mathbf{v}_i$  and  $\mathbf{v}'_i$  the relationship

$$\mathbf{v}_i' = \mathbf{T}_{\mathbf{p}} \mathbf{v}_i \tag{1}$$

holds. With real observations this equality will not hold exactly. The approach taken in ICP is to minimize the Euclidean distance between the corresponding points.

In this work, we project these two models into a virtual range sensor view and minimize the difference between the rendered depths at each point. The projection is done using a rendering operation which uses the hypothesized pose of a model in the camera coordinates to find the intersection of the surface of the terrain model and the rays corresponding to each pixel of the virtual range sensor. The range is then computed as the distance between the camera center and the intersection of the model surface and camera ray.

The rendering takes O(n) operations, where n is the number of pixels in the virtual range sensor. For each

triangle on the mesh  $\mathbf{v}'$ , the vertices  $\mathbf{v}'_i$ ,  $\mathbf{v}'_j$ , and  $\mathbf{v}'_k$  are projected onto the image plane. For every pixel inside that triangle, the location of the intersection of the camera ray  $\hat{\mathbf{n}}_c$  and the facet of the mesh is a point  $\mathbf{s}'_i$ , given by

$$\mathbf{s}_i' = a_i \mathbf{v}_i' + a_j \mathbf{v}_j' + a_k \mathbf{v}_k' \tag{2}$$

with  $a_i + a_j + a_k = 1$ . The depth to the intersection point is the length of the projection of the intersection point onto the camera ray,

$$z_i = \hat{\mathbf{n}}_c \cdot \mathbf{s}_i' \tag{3}$$

The vector of all depths  $z_i$  is denoted z. We fix the registration to use the coordinate frame of the surface model v' so that it does not move during registration. This means that z is a constant and can be computed once at the beginning of a registration.

The depth to the point  $\mathbf{v}_i$  changes with  $\mathbf{p}$ . Similarly to (2) and (3), we write

$$\mathbf{s}_i = \mathbf{T}_{\mathbf{p}}(a_i \mathbf{v}_i + a_i \mathbf{v}_i + a_k \mathbf{v}_k) \tag{4}$$

and

$$h_i(\mathbf{p}) = \hat{\mathbf{n}}_c \cdot \mathbf{s}_i \tag{5}$$

The function h(p) is a vector containing all predicted depths. We define an objective function which is the sum of squared deviations between the projected depths

$$J_2 = \frac{1}{2} (\mathbf{z} - \mathbf{h}(\mathbf{p}))^T \mathbf{R}^{-1} (\mathbf{z} - \mathbf{h}(\mathbf{p}))$$
 (6)

where **R** is the measurement covariance. The use of a rendering model eliminates the need to search for corresponding points. Correspondence between points is established directly by the rendering operation since uncer the current pose hypothesis, corresponding mesh points project to corresponding range image pixels.

# B. Coarse registration

We can expect our rover to have approximate knowledge of translation and rotation between observations. Dead reckoning can provide rudimentary information about both translation and rotation. On relatively short traverses, errors in dead reckoning based purely on odometry on the K9 rover are on the order of 10 cm of translation and a few degrees of rotation in yaw per meter travelled. Our rover also has sensors which measure orientation directly, including an inclinometer and a sun tracker which together fully constrain the rover orientation. These sensors are accurate to within a few degrees regardless of distance travelled.

Visual tracking methods often make use of brute-force correlation to find the 2D image plane location of a feature of interest. Searching for a 6dof rigid transformation using correlation is prohibitive, since evaluating every hypothesis on a 6D grid is expensive. However, if the orientation is approximately known, then 3 of the degrees of freedom can be eliminated, reducing the search to 3dof. Since a virtual range image is used to evaluate each pose hypothesis, we can also eliminate the search in the camera

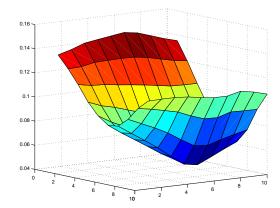

Fig. 3. Example correlation surface for coarse registration.

z axis. For any translation parallel to the camera x-y plane, the average or median z deviation can be computed and removed. This reduces the 6D search to 2D, making correlation feasible.

The correlation proceeds as follows. The camera location and orientation are estimated using onboard sensors, and the orientation is fixed. A grid is established in the camera sensor plane as a set of translations  $\Delta x_c$  and  $\Delta y_c$ . The camera z coordinate of each translation is zero. The approximate camera orientation is then used to rotate these translations to world coordinates  $(\Delta x, \Delta y, \Delta z)$ . For each translation hypothesis, the differences between corresponding pixels in the two rendered range images is computed. The median of these differences is found and subtracted out, and then the sum of absolute differences between the corrected range values is computed as a match score. The match score for each translation in the correlation grid is then interpreted as a correlation surface. The minimum value is chosen as the coarse match. An example correlation surface is shown in Figure 3.

A grid size and grid spacing must be determined over which the correlation is to be computed. Our current implementation uses an  $11 \times 11$  grid with a 10 cm spacing, which can compensate for translation errors of up to half a meter and find an initial coarse alignment that is within 5 centimeters of the solution.

## C. Fine registration

The goal of our registration procedure is to minimize (6). LM requires the gradient and approximate Hessian

$$\nabla_{\mathbf{p}} J_2 = -\mathbf{H}^T \mathbf{R}^{-1} (\mathbf{z} - \mathbf{h}(\mathbf{p}))$$
  
$$\nabla_{\mathbf{p}}^2 J_2 \approx \mathbf{H}^T \mathbf{R}^{-1} \mathbf{H}$$
 (7)

to compute a parameter update

$$\mathbf{p} \leftarrow \mathbf{p} + (\nabla_{\mathbf{p}}^2 J_2 + \lambda \mathbf{I})^{-1} \nabla_{\mathbf{p}} J_2 \tag{8}$$

The parameter  $\lambda$  ensures that (8) is well conditioned and takes an appropriate step. A more complete description of the LM algorithm is beyond the scope of this paper. Several useful descriptions exist[12], [9]. However, the Jacobian of the sensor model is specific to the application described here.

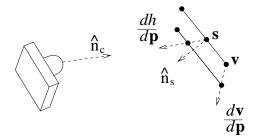

Fig. 4. The Jacobian of the depth measurement is found by projecting the derivative of the vertex locations onto the surface normal.

The Jacobian  $\mathbf{H}$  is the change in the rendered depth at each point with respect to a change in the transformation parameter  $\mathbf{p}$ . Motion of the point  $\mathbf{s}_i$  on a polygon can be decomposed into motion normal to the plane and motion parallel to the plane. Motion parallel to the plane does not change the depth. The depth only changes with motion normal to the plane.

The change of the point  $\mathbf{s}_i$  is described by  $\partial \mathbf{s}_i/\partial \mathbf{p}$ , which is a linear combination of the derivatives  $\partial \mathbf{v}/\partial \mathbf{p}$  with the same coefficients used during rendering in (4). The projection of the derivative onto the surface normal is

$$\frac{\partial \mathbf{s}_i}{\partial \mathbf{p}_{\perp}} = \hat{\mathbf{n}}_c \cdot \left( a_i \frac{\partial \mathbf{v}_i}{\partial \mathbf{p}} + a_j \frac{\partial \mathbf{v}_j}{\partial \mathbf{p}} + a_k \frac{\partial \mathbf{v}_k}{\partial \mathbf{p}} \right) \tag{9}$$

The change in depth  $h_i$  lies along the camera normal. Its projection onto the surface normal is

$$\frac{\partial h_i}{\partial \mathbf{p}_{\perp}} = \hat{\mathbf{n}}_c \cdot \hat{\mathbf{n}}_s \frac{\partial h_i}{\partial \mathbf{p}} \tag{10}$$

Equating the projections (9) and (10) we find

$$\frac{\partial h_i}{\partial \mathbf{p}} = \frac{\hat{\mathbf{n}}_c}{\hat{\mathbf{n}}_c \cdot \hat{\mathbf{n}}_s} \cdot \left( a_i \frac{\partial \mathbf{v}_i}{\partial \mathbf{p}} + a_j \frac{\partial \mathbf{v}_j}{\partial \mathbf{p}} + a_k \frac{\partial \mathbf{v}_k}{\partial \mathbf{p}} \right)$$
(11)

The Jacobian  ${\bf H}$  is the matrix containing all of the gradients  $\partial h_i/\partial {\bf p}$ .

## D. Robust Estimation

The  $L_2$  norm is optimal when the observation noise is Gaussian. However, the  $L_2$  norm may exhibit problems when it is not. For data which contains outliers, there are a family of norms  $\rho()$  which are robust to large deviations. These are functions which have a bounded derivative far from zero, so that large deviations provide only a small contribution to the gradient of the objective function. The objective function used in this work uses the Huber norm[11],

$$\rho(x) = \begin{cases} c^2 (1 - \cos(x/c)) & \text{if } |x|/c < \pi/2\\ c|x| + c^2 (1 - \pi/2) & \text{if } |x|/c \ge \pi/2 \end{cases}$$
 (12)

shown in Figure 5. When the deviation is close to zero, the Huber norm behaves similarly to the  $L_2$  norm. When the deviation is large, the norm behaves similarly to  $L_1$ . This norm has been shown to perform well for ICP[8]. Using the robust norm, we rewrite (6) as

$$J_H(\mathbf{p}) = \frac{1}{2} \sum_{i} \rho(z_i - h_i(\mathbf{p}))$$
 (13)

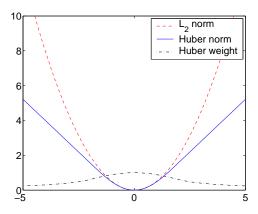

Fig. 5. Comparison of the  $L_2$  norm and the Huber robust norm used in this work, and the weight function for weighted least squares.

and the derivatives as

$$\nabla_{\mathbf{p}} J_{H} = \mathbf{H}^{T} \mathbf{\Omega} \mathbf{R}^{-1} (\mathbf{z} - \mathbf{h}(\mathbf{p}))$$

$$\nabla_{\mathbf{p}}^{2} J_{H} = \mathbf{H}^{T} \mathbf{\Omega} \mathbf{R}^{-1} \mathbf{H}$$
(14)

where  $\Omega$  is a diagonal matrix of weights

$$\omega_{ii} = w(z_i - h_i(\mathbf{p})) \tag{15}$$

The weight function for the Huber norm is

$$w(x) = \begin{cases} c/x \sin(x/c) & \text{if } |x|/c < \pi/2\\ c/|x| & \text{if } |x|/c \ge \pi/2 \end{cases}$$
 (16)

with c=1.2107. The weights are recomputed during each iteration of Levenberg-Marquardt, resulting in an iteratively reweighted least squares algorithm.

## IV. EXPERIMENTAL RESULTS

To empirically validate the performance of the registration for instrument placement, we tested our algorithm with a 4 meter traverse in the laboratory. A stereo image pair was captured using the navigation cameras on the mast of the K9 rover. A 3D model was computed and presented to an operator in the Viz visualization tool. The user specified a goal point on a rock. The selected instrument placement goal location is marked with a "+" in the left camera image shown in Figure 8. The rover moved 4 meters, stopping every meter to align the 3D model of the current view of the goal location with the 3D model created from the initial view. At a distance of 2 meters, the view switched from the navigation cameras on the mast to the hazard cameras on the underside of the rover chassis in order to provide a better view of the goal. This was accomplished using our target handoff by aligning views from the two different camera pairs.

Figure 6 shows two 3D models. The red model is the initial 3D model computed using stereo vision from a distance of 4 meters. The arrow indicates the goal location selected by the rover operator. The textured model is the final view of the rock from the hazard cameras at a distance of 50cm. The misregistration is a result of errors in by dead reckoning, rover kinematics, pan tilt unit calibration, etc. Figure 7 shows the result of aligning the

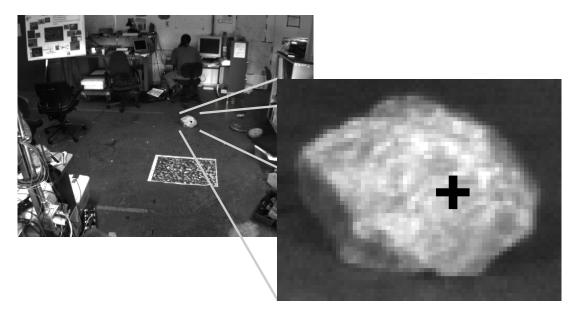

Fig. 8. Selected goal location

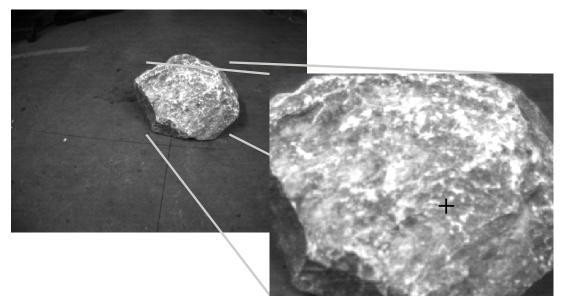

Fig. 9. Estimated goal location after registration

initial model from the navigation cameras with the final model from the hazard cameras.

The goal location on the rock can be recovered directly using the transformation which aligns the views, which is represented with an arrow in Figure 7. The final camera view of the goal is in Figure 9, with the estimated goal location indicated with a "+". This is the intended location for the instrument, which is placed using the algorithms described in[1].

## V. DISCUSSION

Registration of 3D surface models is an attractive method for localization and target approach. As long as the lighting conditions permit the acquisition of images for stereo, the surface models and resulting registration results are independent of the lighting conditions. This

is attractive compared to 2D approaches which might have difficulty with tracking features or recognizing places when lighting conditions change. We can also achieve bounded error in pose estimation with respect to the target location since the initial target model can be used as long as the target remains in view.

Furthermore, 2D visual tracking requires the rover to spend computational effort on computations that it may be doing only for the purpose of visual pose estimation. However, NASA's current plans call for stereo vision to be used for hazard avoidance on MER in 2003 and probably on MSL in 2009. Registering the 3D models that are already created for local path planning and obstacle avoidance makes dual use of data that is being generated anyway. The marginal computation for registration is less than the computation required for building the 3D models

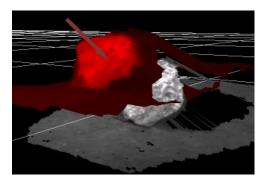

Fig. 6. Terrain models before registration.

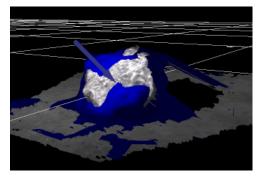

Fig. 7. Terrain models after registration.

in the first place, so most of the computational work is already done.

The robust estimation method used in this paper works quite well. The surface models used in the examples here were not regularized, resampled, or "cleaned" in any way and the results are still promising. Other reported approaches require mesh regularization and cleaning in order to ensure that meshes have similar resolutions and there are no outliers before minimizing a norm which is sensitive to large deviations. These steps may improve the results we can acheive using robust estimation but empirically are not required for it to work.

Algorithmically, our technique compares well to ICP. The rendering operation takes O(n) where n is the number of pixels in the virtual range image. The resolution of the virtual range image can be changed to speed up the algorithm with a corresponding loss in performance due to lack of detail in the models. Levenberg-Marquardt updates require O(n) to construct and multiply matrices, but the computation of the update to the parameter is constant time since the number of dimensions in the parameter vector is fixed at 6. In terms of convergence, the approaches have similar properties since each converges to a local minimum and will find the global optimum if the initial guess is within the basin of attraction. We have not yet done experiments to determine what that basin might look like for the different methods, but we have empirically noticed that the basin of attraction is larger for the robust norm than for least squares. We are working on a more thorough empirical comparison of our technique to ICP, and in the mean time we have also made our 3D terrain data public for interested readers to use for

comparison with other techniques[13].

We are currently working to further extend this work. Algorithmically we are investigating ways to optimize the implementation, perhaps making use of some efficient rendering techniques. We would also like to extend this to multiview registration in order to handle more than two views at a time.

This method is being incorporated into a larger demonstration of single cycle instrument placement for improved efficiency of planetary rovers and increased science return for future Mars missions.
